The most significant balanced element in signed graphs plays a vital role in helping researchers understand the fundamental structure of the graph as it reveals valuable information about the complex relationships between nodes in the network. The challenge is an NP-hard problem; there is no current baseline to evaluate state-ofthe-art signed graphs derived from real networks. In this paper, we propose a scalable state-of-the-art approach for the maximum balanced sub-graph detection in the network of any size although it is still bounded by computational capability. The proposed approach builds on the graph characteristics and a scalable fundamental cycle discovery method to minimize the number of nodes discarded. We evaluate the proposed approach against state-of-the-art and demonstrate over two times higher graph size regarding the number of nodes selected of the discovered subset on an extensive signed network with millions of nodes and edges over the state-of-art in the same time frame.

Signed Network, balance theory, balanced sub-graph

#### **ACM Reference Format:**

# 1 INTRODUCTION

Graphs are widely used to model complex systems in various fields, such as computer science, physics, biology, and social sciences. In contrast to unsigned networks, where all edges are assumed to have positive weights, signed networks allow for negative weights, which may represent antagonistic relationships or conflicting opinions [26]. The largest balanced element in signed graphs plays a crucial role in aiding researchers comprehend the fundamental structure of the graph as it reveals valuable information about the complex relationships between nodes in the network. For instance, the nodes that are part of the maximum balanced sub-graphs are the key players in the system. These nodes may not necessarily have

....

a high degree of centrality between them, but they are essential for understanding how the system behaves. We can gain insight into the mechanisms that drive the system's behavior by identifying these nodes. In addition, it cannot be easy to understand the complex system's behavior. By locating the maximum balanced subgraphs, we can simplify the system into sub-systems with balanced interactions and eliminate inconsistencies regarding unbalanced cycles. The task of the largest balanced sub-graph discovery has applications in portfolio system's economic risk management [11], computational and operational research [8], community analysis and structure [19], computational biology to model balanced interactions between genes and proteins [18] and social network analysis [7]. **Graph** G is an (N,M) set tuple, where N is a set of all nodes of size |N|.

Related Work Finding the optimally balanced sub-graph in a signed graph is known to be an NP-hard problem. Gülpinar et al. proposed the GGMZ algorithm, which begins by computing the input graph's minimum spanning tree. Next, a subset of nodes is selected, and all the edges crossing that subset are inverted to create positive edges. This step is then applied to the entire graph, identifying a set of nodes disconnected by negative edges. This set of nodes is returned as the final output of the "algorithm. The system's overall complexity is  $O(|N|^3)$  if N is a set of nodes [10]. Poljak and Daniel Turzík show that any signed graph that has |N| nodes and |M| edges contains a balanced sub-graph with at least 0.5|M| + 0.25(|N|-1) edges [21]. Crowston et al. propose a discovery of a balanced sub-graph of size 0.5|M| + 0.25(|N|- 1+k), k is a parameter, of the complete system's overall complexity is  $O(|N|^3)$ if N is a set of nodes[10]. The data reduction is based on finding small separators and a novel gadget construction scheme. The fixed-parameter algorithm is based on iterative compression with a very effective heuristic speedup. Figueiredo et al. first introduced a polyhedral-based branch-and-cut algorithm to find an optimal subgraph [9], followed by pre-processing routines and initial heuristic improvements in [8]. The proposed GRASP algorithm randomly selects a subset of vertices. It then greedily adds nodes that maximize the number of edges connecting them to the current subset while keeping the size of the subset balanced [8]. The EIGEN algorithm [3] works by first computing the eigenvectors of the Laplacian matrix of the graph. Using the dominant eigenvector of the adjacency matrix, it then partitions the graph into two disjoint sets. The partition is made by setting a threshold value for the eigenvector and assigning each vertex to one of the two sets based on whether its value in the eigenvector is above or below the threshold. The algorithm then recursively this partitioning process on each of the two sets until the desired level of balance is achieved. Sharma et al. proposed a heuristic that deletes edges from the graph associated with the smallest eigenvalues in the Laplacian matrix of the graph

until a maximum balanced sub-graph is obtained [23]. Ordozgoiti et al. introduced the most scalable version of the algorithm to date. TIMBAL is an acronym for trimming iteratively to maximize balance two-stage method approach where the first stage removes nodes and the second one restores them as long as it does not cause imbalance [20]. Both algorithms rely on signed spectral theory. The approaches do not scale to the large signed graphs as they rely on the costly eigenvalue computation  $(O(|N|^2))$ , and its performance decreases due to the spectral pollution in eigenvalue computation [4]. TIMBAL proposes a novel bound for perturbations of the graph Laplacian pre-processing and sub-sampling techniques to scale the processing for large graphs. The algorithm randomly samples subgraphs and runs TIMBAL. The nodes deleted from at least one of these sub-graphs are then deleted from the original graph. They evaluate the scalability of the proposed work on graphs over 30 million edges by artificially implanting balanced sub-graphs of a specific size and recovering them [20].

This paper proposes an algorithm for balanced consensus discovery (ABCD) in signed graph, and we show that it discovers larger signed sub-graphs faster than TIMBAL. The approach builds on the scalable discovery of fundamental cycles in [2] and utilizes the graph's node density distribution and near-optimal balanced states to minimize the number of nodes removed from the balanced subgraph. The paper is organized as follows: in Section 2, we present preliminary findings; in Section 3, we introduce the ABCD algorithm; in Section 4 we elaborate on the implementation details of the proposed algorithm and evaluation; Section 5, we conduct experiments to compute the number of nodes of the maximum balanced sub-graph of 12 different real-world datasets for our algorithm and compare it to the baseline; in Section 6 we summarize our findings.

# 2 FUNDAMENTAL CYCLE BASIS

In this section, we introduce the concept of a fundamental cycle and present an efficient way to compute fundamental cycles in any graph (it is still limited by computational capabilities). Signed graph  $\Sigma = (G, \sigma)$  consists of underlying unsigned graph G and an edge signing function  $\sigma: M \to \{+1, -1\}$ . The edge *m* can be positive +  $(m^+)$  or negative  $-(m^-)$ . Sign of a sub-graph is product of the edges signs. In a signed graph  $\Sigma$ , a path is a sequence of distinct edges that connect a sequence of distinct vertices. Cycle is a path that begins and ends at the same node. Cycle basis is a minimal set of cycles that allows every even-degree sub-graph to be expressed as a symmetric difference of basis cycles. Connected graph is a graph in which a path joins two vertices. sub-graph is a graph with all edges and nodes in a larger graph. Balanced signed graph is a signed graph where every cycle is positive. Harary bipartition separates the nodes of the balanced graph into two sets such that the nodes of both sets internally agree with each other but disagree with the nodes of the other set[6].

**Fundamental cycle** is a type of cycle sub-graph in a graph created in a specific manner. For the underlying graph G, let T be the spanning tree of G, and let an edge m be an edge in G between nodes x and y that is NOT in the spanning tree T. Since the spanning tree spans all vertices, a unique path in T between nodes x and y does not include m. Therefore, that path in T plus m for a cycle in graph G. A cycle built this way is called a fundamental cycle. A

fundamental cycle basis may be formed from a spanning tree or spanning forest of the given graph by selecting the cycles formed by combining a path in the tree and a single edge outside the tree. For the graph G with |N| nodes and |M| edges, there are exactly |M|-|N|+1 fundamental cycles. It has been shown that using this spanning tree-based approach to discover fundamental cycles and balance the graph requires a minimum number of edge sign switches to produce a balanced graph from the signed graph  $\Sigma$  [22]. The efficient way to discover fundamental cycles is given the spanning tree T [2]. The main benefits of the approach are that labels can be computed with linear time complexity, only require a linear amount of memory, and that the running time for balancing a cycle is linear in the length of the cycle times the vertex degrees but independent of the size of the graph.

# 3 ABCD: ALGORITHM FOR BALANCED COMPONENT DISCOVERY

**Algorithm 1:** Fundamental Cycle Bases with the smallest number of imbalanced fundamental cycles

```
Data: Signed graph \Sigma; IK
   Result: \mathcal{M}_{\Sigma} = M_k, \mathcal{H}_{\Sigma} = H_k, k \in [1, K]
 1 Generate set \mathcal{T}_i of I spanning trees of \Sigma;
 2 Counter to keep only the top nearest balanced states
     i = 0; m_K = m;
3 for i = 0; i++; i < I do
       forall edges m, m \in \Sigma \setminus T_i do
            if fundamental cycle T \cup m is negative then
                add edge m to M_i
 6
       end
7
       if |M_i| < m_K then
8
           \mathcal{M}_{\Sigma} \cup = M_k
       if |\mathcal{M}_{\Sigma}| > K then
            Remove the largest set and update m_K;
11
12 end
13 for i = 0; i++; i < K do
       Create zero vector H_k of dimension n;
14
        for edge m \in M_i do
15
            switch edge sign in \Sigma_k: m^- \to m^+; m^+ \to m^-;
16
        end
17
        Cut all the negative edges to create Harary bi-partitions
         A and B so that |A| > |B|;
        for n in N do
19
            if n \in A, H_k(n) = 1
20
       end
21
22 end
```

The problem we are trying to solve for the signed graph  $\Sigma$  is to identify a sub-graph  $\Sigma'$ ,  $\Sigma' \subset \Sigma$  induced by set of nodes N',  $N' \subset N$ . N is a set of all nodes in graph  $\Sigma$ ,  $\Sigma'$  graph is balanced and the size of N' set is largest possible. This section introduces the Algorithm for the Balanced Component Discovery (ABCD) as a scalable solution for this task, as explained in the following 3 steps. We discover the fundamental cycle bases out of I sampled bases in

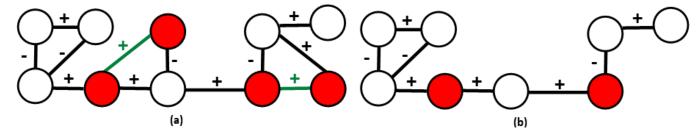

Figure 1: (a): The unbalanced signed network. Green edges are the candidate edges causing imbalance, and red nodes are the candidate vertices. (b): The maximum balanced signed sub-graph obtained after deleting one candidate node along each edge.

the first step. We keep only the K fundamental cycle basis with the smallest number of imbalanced fundamental cycles, as outlined in Alg. 1. The backbone of the proposed algorithm is the fast discovery of fundamental cycles, as introduced in [2] and published in [5]. We integrate the algorithm to identify the fundamental cycle basis for a given spanning tree T. Note that even though we ran the algorithm I >> K times as outlined in [22], we only save the information on the unbalanced fundamental cycles and the Harary bipartition labeling for the top K unique fundamental cycle bases with the lowest cardinality  $|M_K|$ ,  $|M_K| < |M| - |N| + 1$ , as outlined in Alg. 1.

**Algorithm 2:** Computation of the sum of neighborhood degree

Data: Signed graph  $\Sigma$ ;

**Result:** Array neighborhood\_degree

- 1 Declare and initialize array neighborhood\_degree = [];
- **for** v = 0; v + +; v < |N| of  $\Sigma$  **do**
- Declare and initialize integer sum = 0;
- for every neighbor nei connected to v via an edge do
- sum += degree[nei];
- 6 end
- 7 neighborhood\_degree[v]=sum;
- 8 end

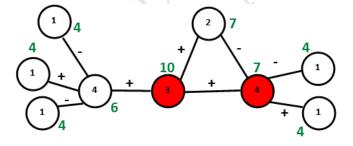

Figure 2: Degree (black, in node) vs. Sum of Neighborhood Degrees (green, next to the node) computation. Sum of neighborhood degrees labels the red nodes connected by a positive link that will be deleted.

In the **second step**, the ABCD algorithm employs a smart edge deletion heuristic for each of the one of K discovered balanced states 2023-07-03 19:32. Page 3 of 1–9.

as it removes all unbalanced fundamental cycles. Our heuristic relies on the notion that minimizing the number of nodes removed from the graph increases the chance that the largest balanced sub-graph has its node cardinality maximized. We have a list of  $M_k$  edges that should have a different sign for the entire graph to be balanced, and we try to minimize the number of edges removed from the graph, as outlined below. We repeat the following steps for all K identified balanced states for a signed graph  $\Sigma$ , and the heuristic on how we remove the unbalanced fundamental cycles out of possible |M|-|N|+1 cycles for the balanced state  $k,k\in[1,K]$  is as follows. First, initialize an empty set of nodes  $N_k$ . Second, for every edge m in  $M_k$  created in Alg. 1 repeat the following:

- (1) If the edge m is positive, it will be negative in the balanced state. If either of the nodes are already in  $N_k$ , move on to the next edge. Else, add the edge-defining node n to  $N_k$  so that  $H_k(n) = 0$ . If they are both 0 or both 1, move this edge to the end of the  $M_k$  set and revisit. If no resolution is offered by  $N_k$  by the end of the process, randomly pick a node. Harary bipartition separates the nodes of the balanced graph into two sets such that the nodes of both sets internally agree with each other but disagree with the nodes of the other set[6]. The  $H_k$  set is created in Alg. 1 as a labeling vector. The logic behind it is that the remaining node is in the largest Harary partition for a fully balanced graph, so it will be connected to more nodes than the node ending up in the smaller Harary set after partitioning.
- (2) If the edge m is negative and marked for switching to positive: if either of the nodes is already in  $N_k$ , nothing needs to be done; move on to the next edge. We add the node with the lower neighborhood degree to  $N_k$ .

The example on how we compute the neighborhood degree for signed vector  $\Sigma$  is illustrated in Fig. 2. Two red nodes in the image indicate the balancing algorithm labeled the edge and that its sign needs to be switched for the graph to achieve a complete balancing state. The degree of the left node is 3, and the right node is 4. However, the neighborhood degree of the left node is 10 (neighbors of a neighbor), and the neighborhood degree of the right node is 7. Thus, we chose the node on the right to delete and the node on the left to keep. If both of them have the same sum of neighborhood degrees, choose the one that is connected to another edge in  $M_k$  set of edges marked to form an unbalanced fundamental cycle. Note

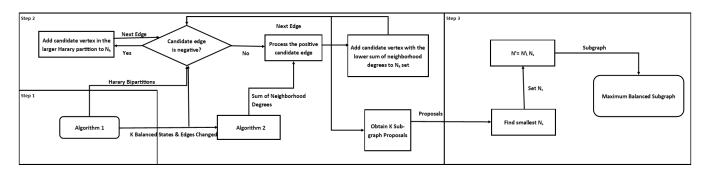

Figure 3: The ABCD pipeline.

that the *neighborhood* degree is computed for all nodes in  $\Sigma$  once and re-used in this step. The algorithm for the computation of the sum of neighborhood degrees is highlighted in Algorithm 2.

In the **third step**, we find the index of the smallest sized  $N_k$  set among all  $N_k, k \in [1, K]$  sets. Let it be index  $s: |N_s| \leq |N_k|, k \in [1, K]$ . The resulting maximized balanced sub-graph proposal  $N_s'$  is finally obtained by removing specific nodes as  $N' = N \setminus N_s$ . We know the remaining subset is balanced as all fundamental cycles in the remaining graph are balanced.

The following are a set of observations have helped refine and shape our method as well as establish an underpinning in which our algorithm stands on:

**Observation 1:** A balanced state with the lowest frustration index for a specific signed network does not necessarily yield a maximum balanced sub-graph using the set of conditions we laid out for processing positive and negative candidate edges (relying on Harary bipartitions for positive edges and sum of neighborhood degrees for negative edges for the decision-making for vertex deletion). However, a balanced state with a high frustration index skyrockets the number of vertices discarded due to the increase in the number of candidate vertices and edges to be processed. Hence, we only capture the information on the unbalanced fundamental cycles and the Harary bipartition labeling for the top *K* unique fundamental cycle bases with the lowest cardinality.

**Observation 2:** Among the tree-sampling techniques such as depth-first search, randomized depth-first search, and breadth-first search, the latter is the most suitable for this kind of task because it relatively reduced the amount of identified candidate edges compared to others.

**Observation 3:** The largest connected component (LCC) produced at the end is *guaranteed* to be balanced. This algorithm eliminates the cycle bases that are unbalanced by leaving a "hole" which prevents any consensus conflict. Therefore, this component is then called the maximum (it has the largest size in terms of the number of vertices) balanced (it has no unbalanced cycles) sub-graph (the number of nodes in this component is less than or equal to that of the entire signed network input) where edge sign switching is absent.

# 4 METHODOLOGY

**Implementation** The entire code is implemented in C++. The implementation first identifies the largest connected component (LCC)

in the supplied network and only applies the ABCD algorithm to that component. All benchmark graphs have one large connected component, so the findings do not take away from the generalizability of the method. The implementation treats edges without signs as positive edges in the fundamental cycle. If the graph has more equal connected components, the implementation can be easily extended to accommodate that scenario. Step one of the code implementation of the algorithm presented in Alg. 1 builds on fundamental cycle discovery code release [5]. Recent findings have shown that the breadth-first search approach for sampling the spanning tree from the graph was diverse enough. Its implementation was faster than the adapted version for other samplers of a given signed graph  $\Sigma$  [24], and we adopt the breath-first search method for sampling spanning trees in the Algorithm 1. Iterations are set to 5000 when running ABCD on all signed networks. For small signed networks (Highland, CrisisInCloister, ProLeague, DutchCollege, and Congress) K is set to be high K = 4000 as processing is fast. We set K = 100 for larger Konect and Amazon datasets with under 300,000 nodes. For large signed graphs derived from Amazon ratings, K is set to 20. We implement the rest of the algorithm as outlined in Section 3. In the third step,  $N'_s$  is constructed by the algorithm re-reading the original graph and skipping the entries with nodes in  $N_s$ . The code and data are released in the anonymous GitHub repository for review [1].

Datasets We evaluate the proposed ABCD algorithm on two signed graph benchmarks. The first set comprises 14 signed graphs from the Konect repository [16] used in [20] (except TwitterReferendum and PPI which are not from the Konect site). The second set is the set of 17 Amazon rating files [12] also used in [2]. Konect Signed Graphs Konect signed graphs and their characteristics are described in Table 1. Highland is the signed social network of tribes of the GahukuGama alliance structure of the Eastern Central Highlands of New Guinea, from Kenneth Read [16]. CrisisInCloister is a directed network that contains ratings between monks related to a crisis in a cloister (or monastery) in New England (USA) which led to the departure of several of the monks [16]. ProLeague are results of football games in Belgium from the Pro League in 2016/2017 in the form of a directed signed graph. Nodes are teams; each directed edge from A to B denotes that team A played at home against team B. The edge weights are the goal difference, and thus positive if the home team wins, negative if the away team wins, and zero for a draw [16]. DutchCollege is a directed network that contains friendship ratings between 32 university freshmen who mostly did

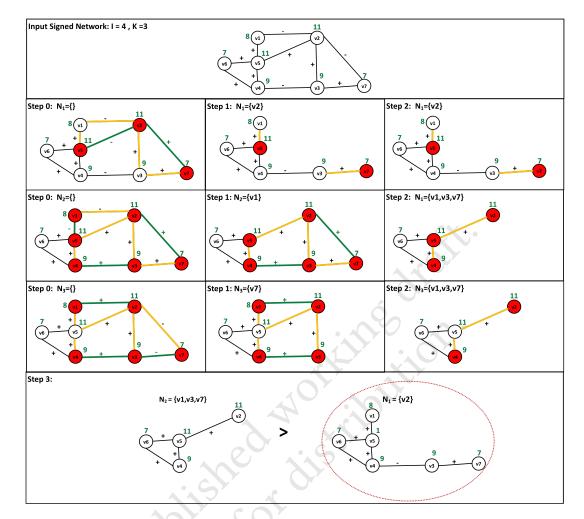

Figure 4: The ABCD algorithm. Balancing occurs in Step 0 with green text on the edges with the changed signs. Green numbers beside nodes are the sum of neighborhood degrees. Orange edges are the edges of the unbalanced fundamental cycles. Green edges are the candidate edges. Red nodes are the candidate nodes for deletion. The red dotted oval over the graph in Step 3 signifies that the final output  $N_s'$  of ABCD has a maximal cardinality.

not know each other before starting university. Each student was asked to rate the other at seven different time points. A node represents a student, and an edge between two students shows that the left rated the right. The edge weights show how good their friendship is in the eye of the left node. The weight ranges from -1 for the risk of conflict to +3 for best friend [16]. Congress is a signed network where nodes are politicians speaking in the United States Congress, and a directed edge denotes that a speaker mentions another speaker [16]. In the Chess network, each node is a chess player and a directed edge represents a game with the white player having an outgoing edge and the black player having an ingoing edge. The weight of the edge represents the outcome [16]. BitcoinAlpha is a user-user trust/distrust network from the Bitcoin Alpha platform on which Bitcoins are traded [16]. BitcoinOTC is a user-user trust/distrust network, from the Bitcoin OTC platform, on which Bitcoins are traded [16]. TwitterReferendum captures data from Twitter concerning the 2016 Italian Referendum. Different

stances between users signify a negative tie, while the same stances indicate a positive link [17]. WikiElec is the network of users from the English Wikipedia that voted for and against each other in admin elections [16]. Slashdot is the reply network of the technology website Slashdot. Nodes are users, and edges are replies [16]. The edges of WikiConflict represent positive and negative conflicts between users of the English Wikipedia [16]. WikiPolitics is an undirected signed network that contains interactions between the users of the English Wikipedia that have edited pages about politics. Each interaction, such as text editing and votes, is given a positive or negative value [16]. *Epinions* is the trust and distrust network of Epinions, an online product rating site. It incorporates individual users connected by directed trust and distrust links [16]. PPI is a signed protein-protein interaction network between 3, 058 proteins [25] [13]. The characteristics of the signed graphs are listed in Table 1.

Table 1: Konect (except TwitterReferendum and PPI which are not from the Konect site) graph attributes: |N| is the total number of vertices; |M| is the total number of edges in the graph; The number of edges of the entire input signed network is the reported numbers from the Konect site. The number of edges of LCC is computed locally in our machine with pre-processing techniques such as removing duplicate and inconsistent edges are applied.

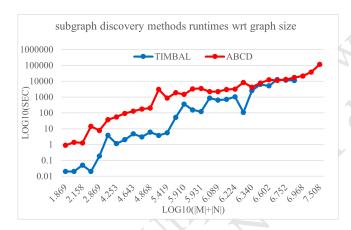

Figure 5: TIMBAL algorithm and ABCD algorithm are linear with the graph size |M| + |N| for all signed graphs tested.

# 5 RESULTS

**Amazon Signed Graphs** benchmark consists of 17 signed graphs derived from the Amazon rating and review files [12]. The dataset contains product reviews and metadata from Amazon, spanning May 1996 - July 2014. We use the Amazon rating dataset as (user, item, rating, timestamp) tuples for these experiments. We also use a smaller version of Digital Music (64,706 reviews), Musical Instruments (10,261 reviews), and Amazon Instant Video (37,126 reviews) ratings, where there are five or more reviews provided per product. Rating score is mapped into an edge between the user and the product as follows  $(5,4) \rightarrow m^+, 3 \rightarrow m$  (no sign), and  $(2,1) \rightarrow m^-$  [12]. The summary of the datasets is outlined in Table 2.

**Setup** TIMBAL [20] approach has been shown to reach the highest cardinality of the sub-graphs in various datasets and is a de-facto

state of the art [20]. ABCD is run on the same graphs as TIMBAL, and the results are compared side-by-side for 14 Konect and 17 Amazon datasets in terms of runtime in seconds and the size of the produced sub-graph. The input parameters of TIMBAL [14] are set as follows for all subsample flag=False, samples=4 based on the paper implementation. The parameter max removals=1 is set for small graphs such as Highland, CrisisInCloister, ProLeague, DutchLeague, and Congress, and it is set to max\_removals=100 for the rest of the signed networks. We set avg size=20 for datasets of several nodes less than 80,000, and subsample\_flag=True, samples = 1000, avg size = 200 max removals=100 for datasets with the number of nodes greater than 80,000. TIMBAL is a non-deterministic algorithm, and we run it 5 and 10 times for Konect data to get the maximum node cardinality. All ABCD parameters are fixed, as described in the implementation section. The operating system used for the experiments is Linux Ubuntu 20.04.3, running on the 11th Gen Intel(R) Core(TM) i9-11900K @ 3.50GHz with 16 physical cores. It has one socket, two threads per core, and eight cores per socket. The architecture is X86 x64. GPU is Nvidia GeForce having 8GB memory. Its driver version is 495.29.05, and the CUDA version is 11.5. The cache configuration is L1d: 384 KiB, L1i: 256 KiB, L2: 4 MiB, L3: 16 MiB. The CPU op is 32-bit and 64-bit.

Konect benchmark consists of 14 Konect datasets, and TIMBAL and ABCD performance are outlined in Table 3 ABCD matches TIMBAL performance in the smallest three networks and *Congress* data and takes a slightly longer time. ABCD algorithm finds a more significant subset for relatively small *DutchCollege*, BitcoinAlpha, BitcoinOTC, Chess, TwitterReferendum [17], SlashdotZoo, PPI [25], and Epinions [16]. TIMBAL performs better on the three Konect Wiki data sets. While Timbal is significantly faster than ABCD on smaller networks, it is only double the speed for the Epinions network of 119,000+ nodes, and ABCD recovers the largest balanced sub-graph. The comparison graphs are outlined in Figure 6(right). We recorded the maximum number of vertices obtained after 5 and 10 runs for TIMBAL, and only for one dataset did the repeated runs discover a larger subset.

For bipartite Amazon graphs, a single TIMBAL run takes as long as ABCD. Moreover, ABCD has a superior runtime and performance regarding the graph size it discovers, as illustrated in Table 4. TIMBAL's performance degrades with the graph size, and the discovered sub-graphs are much smaller than what ABCD finds; see Figure 7(left) for comparison. Figure 5 illustrates a single TIMBAL run time and ABCD run time as a function of the graph size for all Konect and Amazon graphs. Both algorithms have approximately run times linear with the size of the graph. ABCD's performance in the most extensive sub-graph discovery is superior to TIMBAL. TIMBAL performance significantly degrades in terms of balanced graph recovery for all graphs over 350,000 nodes.

# 6 CONCLUSION AND FUTURE WORK

We propose a novel scalable algorithm for balance component discovery (ABCD). We demonstrate that it recovers much more significant (over two times) balanced sub-graphs than state-of-art for large signed graph networks while keeping the processing time linear with the size of the graph. Finding maximum balanced sub-graphs is a fundamental problem in graph theory with significant practical

Table 2: Amazon ratings and reviews (a subset of Amazon ratings constructed from core5 reviews) [12] mapped to signed graphs. The number of vertices, edges, and cycles reflect the number in the largest connected component of each dataset.

Amazon	Input graph	<b>Largest Connected Component</b>				
Ratings	# ratings	# nodes	# edges	# cycles

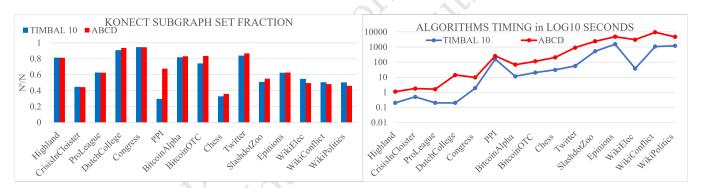

Figure 6: ABCD and TIMBAL performance comparison from Table 3). The largest connected component of Konect graphs is close to the size of the graph, and both methods retrieve similarly size portions of the graphs. ABCD performs better for seven graphs, TIMBAL for three wiki graphs, and they score equally on three smaller graphs.

applications. While the situation is computationally challenging, the existing heuristic algorithms have made considerable progress in solving it efficiently for many signed networks. In this paper, we proposed a novel framework for this problem to improve the results of the latest baseline on 90% real-world signed networks we have tested in terms of runtime scale and the size of sub-graphs in terms of the number of nodes included. Recently, Kundu et al. proposed faster O(|M|) heuristic and efficient implementation for balancing a graph and for typically obtaining a lower number of flips to reach consensus [15] than [2]. Their paper suggests that edges, regardless of whether they belong to the spanning tree, can be chosen to be switched for balance. We plan to investigate this next, as multiple unbalanced fundamental cycles can share an edge in the spanning edge. Changing the sign of a tree edge might cause

processing instabilities. Next, even on the most significant input with 10M nodes and 22M edges, the GPU code takes less than 15 minutes to compute 1000 nearest balanced states, i.e., under 1 second per sample [2]. Since the runtime is roughly proportional to the input size, the ABCD implementation should be able to balance inputs that are ten times larger in a few seconds per sample, making it tractable to analyze graphs with 100s of millions of nodes and edges. Future work includes integrating the OpenMP and GPU code accelerations.

Table 4: Amazon ratings and reviews graph characteristics [12]. The number of vertices, edges, and cycles reflect the number in the largest connected component of each dataset. The time in seconds for TIMBAL is the total time. For graphs over million nodes, we had only data on one run as it takes over 100 minutes per run for TIMBAL. The time in seconds for ABCD includes 5000 iterations. N/A indicates that a method does not terminate within 2 days.
